Structure prediction of ordered and disordered multiple octahedral cation perovskites using SPuDS

The software package SPuDS has previously been shown to accurately predict crystal structures of $AMX_3$ and $A_1-A'_1MX_3$ perovskites that have undergone octahedral tilting distortions. This paper describes the extension of this technique and its accuracy for $A_2MM'X_6$ ordered double perovskites with the aristotype $Fm\overline{3}m$ cubic structure, as well as those that have undergone octahedral tilting distortions. A survey of the literature shows that roughly 70% of all ordered double perovskites undergo octahedral tilting distortions. Of the 11 distinct types of octahedral tilting that can occur in ordered perovskites, five tilt systems account for ~97% of the reported structures. SPuDS can calculate structures for the five dominant tilt systems, $Fm\overline{3}m (a^a a^a)$, $I4/m (a^a a^a c^c)$, $R\overline{3} (a^a a^a a^a)$, $I\overline{2}m (a^6b^6c^6)$ and $P2_1/n (a^a a^b b^b)$, as well as two additional tilt systems, $Pn\overline{3} (a^a a^a)$ and $P4/mnc (a^a a^a c^c)$. Comparison with reported crystal structures shows that SPuDS is quite accurate at predicting distortions driven by octahedral tilting. The favored modes of octahedral tilting in ordered double perovskites are compared and contrasted with those in $AMX_3$ perovskites. Unit-cell pseudosymmetry in Sr- and Ca-containing double perovskites is also examined. Experimentally, Sr$_2MM'O_6$ compounds show a much stronger tendency toward pseudosymmetry than do Ca$_2MM'O_6$ compounds with similar tolerance factors.

1. Introduction

Structures in the $AMX_3$ family of perovskites have been extensively investigated because of the considerable interest in structural variations and their correlation with physical properties. The perovskite material class exhibits interesting and diverse physical properties including ferroelectricity, piezoelectricity, superconductivity, magnetoresistance and ionic conductivity, among others. All of these physical properties are sensitive to subtle changes in the structure, particularly those that result from tilting of octahedra. Consequently, the crystal structures of many perovskites have been investigated, as have the favored modes of octahedral tilting in ternary $AMX_3$ perovskites (Lufaso & Woodward, 2001). Introducing two or more cations on the octahedral site (i.e. $M$ and $M'$ in $AM_{1-x}M'_xO_3$) greatly expands the perovskite family, to the extent that perovskites make up one of the largest families of complex oxides. The scope of the perovskite family is further expanded when non-oxide (halides, sulfides, oxynitrides etc.) compositions are included. If the charge difference between $M$ and $M'$ is small and the ionic radii are similar then the two different octahedral cations may form a solid solution with a disordered octahedral cation sublattice. More commonly the octahedral cations adopt an ordered or partially ordered distribution. Ordering of the octahedral

† The number in parentheses corresponds to the numbering of the tilt systems originally adopted by Glazer (1972).

gations is particularly common when • site cation ordering, with • site cations is crystallographically equivalent, and • site cations occupy multiple crystallographic sites. An octahedral tilting distortion occurs when the • site cation is too small for the cubo-octahedral cavity of the corner-sharing octahedral network. Notations to describe various types of octahedral tilting distortions were developed independently by Aleksandrov (1976) and Glazer (1972). Throughout this text we will use the notation of Glazer. Both octahedral tilting distortions and the formation of an ordered cation arrangement induce a change of the unit-cell size and space-group symmetry. The reader is referred elsewhere for a more complete description of the space-group symmetries and unit-cell sizes of perovskites resulting from a combination of octahedral tilting and • site cation ordering (Aleksandrov & Misyul, 1981; Woodward, 1997a; Bock & Müller, 2002; Howard et al., 2003; Howard & Stokes, 2004, 2005).

As was shown in the preceding article and discussed previously in the literature (Howard et al., 2003), cation ordering makes the task of identifying out-of-phase tilting more difficult. Therefore, the possibility of incorrect space-group assignment is even higher among ordered perovskites than it is among ternary perovskites. Increased structural complexity in double perovskites leads to more degrees of freedom, thus increasing the number of variables and making the structure solution and refinement process more difficult (particularly when pseudosymmetry is severe). In order to obtain the correct crystal structure, good starting models are needed for structural refinements. This argument provided the motivation to expand the capabilities of the software program SPuDS (Lufaso & Woodward, 2001), which previously was able to model •X and • •X perovskites only, to handle ordered double perovskites. Modeling capabilities have been extended to calculate optimized crystal structures in the most commonly observed space groups for rock-salt ordered double perovskites: Fm3m (a•a•d•d•), I4/m (a•d•c•c•), P4/nmm (a•a•c•), R3 (a•a•a•), I2/m (a•b•b•), Pn3 (a•a•a•) and P2/n (a•a•b•).

It is anticipated that the capability to predict the crystal structures of ordered double perovskites will find a number of uses. Physical properties can be estimated from SPuDS-generated structures using computational tools for hypothetical compositions or those compounds where reliable structural data are not available. SPuDS can be used as a guide for exploratory synthetic efforts by quickly finding ion combinations that can adopt the perovskite topology with minimal bond strains. The structures generated by SPuDS possess perfectly regular octahedra, whereas in real crystals this is often not strictly true. Therefore, comparisons between the observed and calculated structures enable one to deconvolute the effects of octahedral tilting from other distortion mechanisms. A nice illustration of this process can be found in the recent paper by Zhou & Goodenough (2005). Finally, SPuDS provides excellent starting models for use in Rietveld refinements, allowing one to test easily a variety of tilt systems for agreement with the experimental data. This application may help to reduce the number of erroneous structure reports that, unfortunately, are fairly common in the perovskite literature.

2. Survey of octahedral tilting in ordered double perovskites

The space-group symmetry, degrees of freedom, number of Wyckoff sites per ion and the frequency of literature reports for each tilt system are shown in Table 1. The tilt systems have been subdivided into two categories: group A, where all • site cations are crystallographically equivalent, and group B, where the • site cations occupy multiple crystallographic sites. It has been shown in •X perovskites that tilt systems belonging to group A are strongly preferred over those belonging to group B, except in cases where ions with distinctly different sizes occupy the • site (e.g. CaCu2TiO4; Woodward, 1997c). Table 1 shows that a similar trend holds for ordered perovskites. In fact, it is only recently that ordered perovskites belonging to group B have been reported (Byeon et al., 2003, 2004).

While it is true that, in general, the preferred tilt systems of ordered •X and • •X perovskites are
similar to the preferences of AMX$_3$ and A$_1$-$A'_1$MX$_3$ perovskites, there are some differences. Among ordered double perovskites the undistorted aristotype cubic structure accounts for $\sim$30\% of the reported structures for oxides and almost all of the halides. In contrast, less than $\sim$10\% of AMX$_3$ perovskites adopt the undistorted cubic structure at room temperature and pressure. The rhombohedral $a^a$$a^a$$c^c$-tilt system is more common among AMX$_3$ perovskites, whereas the tetragonal $a^0$$a^0$$c^-$-tilt system is more prevalent among ordered perovskites. There are numerous examples of $a^a$$a^a$ tilting among $A'A_1$MX$_3$ compositions but few analogues amongst $A'A_1$M$_2$M'$_2$X$_{12}$ ordered perovskites. These differences between ordered double perovskites and simple perovskites are investigated in more detail in §4.

3. Experimental – SPuDS calculation method

The algorithm utilized in the SPuDS crystal structure calculations has been described previously (Lufaso & Woodward, 2001). Therefore, our discussion is limited to a brief overview and a summary of new features. Unconstrained optimization of the crystal structure requires determination of the unit-cell and a summary of new features. Unconstrained optimization

2 Postulated bond-valence parameters, $R_{ij}$, included in SPuDS that are not included in the tabulation by Brown [http://www.ccp14.ac.uk/cci/web-mirrors/i_d_brown] are $R(Fe^{2+}-O^-) = 1.908$, $R(Sc^{3+}-O^-) = 1.890$, $R(Sc^{3+}-O^-) = 1.952$, $R(Pt^{4+}-O^-) = 2.077$, $R(Re^{6+}-O^-) = 1.949$, $R(Rh^{3+}-O^-) = 1.8$ and $R(Tb^{3+}-O^2-) = 1.997$ with $b = 0.37$.

3 Lattice parameters are reported to the nearest 0.0001 Å and 0.01°. The fractional coordinates are reported to the nearest 0.001.

4 The tolerance factor, $\tau$ (Goldschmidt, 1926), describes the fit of the A-site cation in the cavity formed by the corner-sharing octahedra and may be used to estimate the occurrence and magnitude of the octahedral tilting distortion.
range of tolerance factors than their \(AMX_0\) counterparts. The enhanced stability of the undistorted cubic structure among ordered perovskites can be understood, in part, by considering the forces that favor second-order Jahn–Teller (SOJT) distortions of the octahedral site cations (Halasymami & Poeppelmeier, 1998; Halasymami, 2004). Classic examples of this include BaTiO\(_3\) (\(t = 1.06\)) (Kwei et al., 1993) and KNbO\(_3\) (\(t = 1.06\); Hewat, 1973), both of which undergo a series of symmetry-breaking phase transitions upon cooling, which involve displacements of the \(M\)-site cations. Strong covalent bonding between the \(d^0\) transition metal ion and oxygen drives these displacements. In the case of BaTiO\(_3\) the oversized Ba\(^{2+}\) ion places the Ti–O bonds under tension, thereby inducing the titanium displacements. Similar distortions do not occur in the ATiO\(_3\) series when the \(A\)-site cation is the right size, as is the case with SrTiO\(_3\) (\(t = 1.00\); Hutton et al., 1981), or too small, as is the case with CaTiO\(_3\) (\(t = 0.95\); Sasaki et al., 1987).

In contrast, niobium displacements persist in NaNbO\(_3\) (\(t = 0.97\); Sakowski-Cowley et al., 1969) and are also present in WO\(_3\) (Howard et al., 2002; Woodward et al., 1997), where there is no \(A\)-site cation at all. The metal–oxygen covalency in these two compounds is sufficiently high that the occurrence of SOJT distortions is not dependent on bond strains introduced by the \(A\)-site cation.

SOJT distortions involving the octahedral cations are much less common in ordered perovskites, increasing the population of the \(d^0d^0\) tilt system among \(A_2MM'X_6\) perovskites when \(t > 1\). The paucity of octahedral site SOJT distortions among ordered perovskides can be understood by considering the bonding at the \(O\) atoms. As an example, consider the bonding in the tetragonal form of KNbO\(_3\). The niobium ion displaces toward the oxygen ion that lies immediately above it, producing a short Nb—O bond. This distortion leads to an overbonding at the oxygen site that is compensated for by a parallel displacement of the niobium ion in the neighboring octahedron away from the oxygen. This type of cooperative displacement creates one short and one long Nb—O bond, thereby maintaining a reasonable bond valence for oxygen. In an ordered double perovskite, such as Ba\(_2\)MgWO\(_6\), typically only one of the octahedral site cations has the proper electron configuration (\(d^0\)) to favor a SOJT distortion. As a consequence, if the W\(^{6+}\) ion displaces to form a short W—O bond, the overbonding at oxygen cannot be relieved because the neighboring Mg\(^{2+}\) cation is not prone to displace and create the long Mg—O bond needed to maintain an appropriate bonding interaction at oxygen. This situation effectively destroys the cooperativity of the W\(^{6+}\) displacements and dampens the soft modes associated with displacements of these ions. Ferroelectric or antiferroelectric type displacements of \(d^0\) transition metal ions on the octahedral site in ordered double perovskides typically occur only through coupling with lone-pair cations, which are also SOJT active, on the \(A\)-site. Examples include Pb\(_2\)MgWO\(_6\) (Baldinnozzi et al., 1995) and Pb\(_2\)ScTaO\(_6\) (Woodward & Baba-Kishi, 2002).

While SOJT distortions are not common in ordered perovskites, there is no doubt that the \(M—X\) bonds are placed under tension when \(t > 1\). In order to model accurately the crystal structures of \(d^0d^0\) double perovskides, two calculation schemes were developed. The standard calculation method fixes the \(M—X\) bond distances at the beginning of the process, thereby fixing both degrees of freedom and leaving the \(A\)-site cation overbonded. This shortcoming led us to introduce a second calculation method that takes into account these competing bond strains. The lattice parameter and fractional coordinate of the anion are first calculated in the standard manner. The lattice parameter is then varied until the GII reaches a minimum value. As a quantitative comparison of these two approaches consider the
agreement between the calculated and observed values of the lattice parameter, as illustrated in Fig. 1(a). Not surprisingly the first calculation method (filled triangles) overestimates the lattice parameter when \( \tau < 1 \) and underestimates the lattice parameter when \( \tau > 1 \), because the role of the \( A \)-site cation is completely neglected. A more accurate prediction of the lattice parameter was obtained by allowing the octahedral bond distances to vary, particularly in the calculation of the lattice parameters for structures with \( \tau < 1 \). Using this latter method the error in the lattice parameter is typically less than 1.5%. Fig. 1(b) shows the calculated and observed values of the anion coordinate \( x \) as a function of the difference in the ionic radii of octahedral site cations, \( r(M) - r(M') \). Here the agreement between calculation and experiment is even better. Finally, Fig. 1(c) shows the deviation of the bond-valence sum for each ion from its formal oxidation state. The trends are pretty much as expected. When \( \tau < 1 \), the \( A \)-site cation is underbonded and the octahedral site cations are overbonded, whereas with \( \tau > 1 \), the opposite trends are observed. It is interesting and perhaps not intuitive to note that regardless of tolerance factor the \( O \) atom retains a bond-valence sum that shows little deviation from its ideal value of 2. Once again the sometimes neglected bonding preferences of the anion are seen to be critical in directing structure.

4.2. \( I4/m (a^0a^0c^0) \) and \( P4/mnc (a^0a^0c^0) \)

Imposition of a single rotation of the octahedra about one of the fourfold axes destroys the threefold axes and the perpendicular fourfold axes, lowering the symmetry to tetragonal. Out-of-phase rotations of the octahedra, \( a^0a^0c^0 \), lead to a structure with \( I4/m \) symmetry, while in-phase rotations of the octahedra, \( a^0a^0c^0 \), lead to a structure with \( P4/mnc \) symmetry. Only one double perovskite system, \( Ba_2PrRu_1IrlO_6 \), has been reported to crystallize with the \( P4/mnc \) structure (Li & Kennedy, 2004). It is worth mentioning that \( Ba_2PrIrO_6 \) was subsequently reported to crystallize in space group \( Fm\overline{3}m \) (Fu & Ijdo, 2005a). The fractional positions in the structure with \( P4/mnc \) symmetry are \( A (0, \frac{1}{2}, \frac{1}{2}) \), \( M (0, 0, 0) \), \( M' (\frac{1}{2}, 0, \frac{1}{2}) \) and \( X_1 (0, 0, z) \) with \( z \approx \frac{1}{4} \), and \( X_2 (x, y, 0) \) with \( x \approx \frac{1}{4} \) and \( y \approx \frac{1}{2} \).

The \( I4/m (a^0a^0c^0) \) structure is the much more common variety of tetragonal ordered double perovskite. The fractional positions are \( A (0, \frac{1}{2}, \frac{1}{2}) \), \( M (0, 0, 0) \), \( M' (\frac{1}{2}, 0, \frac{1}{2}) \), \( X_1 (0, 0, z) \) with \( z \approx \frac{1}{4} \), and \( X_2 (x, y, 0) \) with \( x \approx \frac{1}{4} \) and \( y \approx \frac{1}{2} \). Table 3 lists examples of \( A_2MM'X_6 \) perovskites and compares the structural parameters predicted by \( SPuDS \) with the reported values. \( Ba_2CuTeO_6 \) and \( Ba_2CuWO_6 \), and the analogous \( A = Sr \) compounds stand out from the rest of the entries because (a) they have large tolerance factors and (b) the value of \( 2^{12}/a'c'c \) is much smaller than predicted by \( SPuDS \). The latter trend can easily be understood by recognizing that the octahedron surrounding the \( Cu^{2+} \) ion will undergo a large axial elongation owing to a first-order Jahn–Teller distortion (Lufaso & Woodward, 2004). Even without octahedral tilting, the Jahn–Teller distortion will lower the symmetry from cubic to tetragonal. It seems likely that the primary distortion

---

**Figure 1**

(a) Percent lattice error for fixed \( M-X \) and \( M'-X \) and GII optimized structures versus tolerance factor for tilt system \( a^0a^0c^0 \) (\( Fm\overline{3}m \)). Percent lattice error is defined as \( \left[ \left( a_{obs} - a_{theo} \right) / a_{theo} \right] \times 100 \), where \( a_{theo} \) and \( a_{obs} \) are the \( SPuDS \) predicted and experimentally observed lattice parameters, respectively. Open squares represent the GII and filled triangles represent fixed \( M-X \) and \( M'-X \) optimized crystal structures. (b) Oxygen fractional coordinate \( x \) versus \( r(M) - r(M') \), where \( r(M) \) is the radius of the \( M \) cation at the origin and \( r(M') \) is the radius of the \( M' \) cation at \((\frac{1}{2}, 0, 0)\). Open diamonds represent observed values and filled circles represent the predicted value. (c) Bond-valence sum minus the formal oxidation state for the experimental crystal structures versus tolerance factor. Circles represent the \( A \) cation, filled triangles the average \( M \) cation and squares the \( O \) atom.
mechanism in these compounds is the Jahn–Teller distortion, and the out-of-phase octahedral tilts are a secondary distortion mechanism. This fact helps to explain why the tolerance factors of these compounds deviate from the rest of the examples in Table 3. Excluding compounds that contain a Jahn–Teller ion (Cu$^{2+}$ or Mn$^{3+}$) on one of the octahedral sites, there are two commonalities among the oxides that adopt the I4/m structure. First, the tolerance factors of these compounds fall over a fairly narrow range, roughly from 0.99 to 0.97. Secondly, the A-site cation is Sr$^{2+}$ in the vast majority of cases. Of course, these two observations are not entirely independent of each other, but it is worth noting that a number of examples of Ba$_2$M'M'O$_6$ compounds with tolerance factors in the range 1.00–0.97 can be found among the cubic perovskites in Table 2.

The accuracy of the structural parameters predicted by SPuDS in Table 3 is reasonably good, but there are some common trends in the discrepancy between observed and calculated values. These trends can be seen more easily when the data are displayed graphically. The observed and calculated values of the M–O–M' bond angles in the xy plane are shown in Fig. 2(a). As expected, the octahedral tilt angle smoothly increases as the tolerance factor decreases in both the calculated and the observed structures. The octahedral tilt angle is consistently predicted to be ~2.5° larger than observed, although admittedly there are a number of points that do not obey this relationship. The observed and calculated values of the c/(21/2a) ratio, which is a measure of the tetragonal distortion, are plotted in Fig. 2(b). As $r$ decreases the octahedral tilting increases causing the a axis to contract and the c/(21/2a) ratio to increase. Once again the calculations and observations follow the same trend, but the calculations consistently overestimate the c/(21/2a) ratio. This can be traced in part to the overestimation of the octahedral tilting. The dashed line in Fig. 2(b) shows what the c/(21/2a) ratio would be if the octahedral tilt angle was smaller by 2.5° but the octahedra remained perfectly regular.

Finally we should note that the minimum GII value that can be obtained with either the $a^0b^0c^0$ or the $a^0b^0c^+$ tilt system is somewhat higher than the minimum GII value that can be obtained assuming $a^0a^0a^0$ or $a^0a^0b^+$ tilting. Clearly the GII cannot be used blindly to predict the most stable tilt system, particularly when the octahedral tilting distortion is fairly small. In such cases additional factors need to be taken into account to determine the most stable structure. Furthermore, most perovskites that have tolerance factors that are a slightly smaller than the unity undergo transitions to other tilt systems as a function of temperature. Thus, the energetic differences between competing tilt systems are necessarily small.

4.3. I2/m ($a^0b^+b^-$)

The combination of two out-of-phase tilts of equal magnitude about the a and b axes of the cubic cell, tilt system $a^0b^+b^-$, is the equivalent of a single tilt, $\theta$, about the [011] direction of the aristotype structure. The combination of rock-salt cation ordering and $a^0b^+b^-$ tilting produces a structure...
with \(P2_1/n\) space-group symmetry. The fractional positions are \(A(0,0,0)\), \(M(0,0.25,0.375)\), \(M'(0.25,0.375,0)\), \(X_1(0.6,0,0)\), and \(X_2(0.6,0.5,0)\). There are relatively few reported examples of \(a^2b^-\) ordered perovskites. Oxide examples are listed in Table 4, together with a comparison of the calculated and reported values of key structural variables. Recently, Sr\(_2\)CoTeO\(_6\) was suggested to undergo a phase transition from space group \(Fm\overline{3}m\) at 373 and 773 K, respectively; however, complete crystal structures were not reported (Ortega-San Martin et al., 2005). It is interesting to note that many of the compounds in Table 4 contain a main group ion in a high oxidation state (Bi\(^{5+}\), Sb\(^{5+}\) and Te\(^{6+}\)). This situation is in contrast to members of the \(a^3a^1\) tilt system where transition metal ions, particularly \(d^1\) transition metal ions, are more prevalent (see Table 3). Once again we see a tendency for the calculations to overestimate the magnitude of octahedral tilting. In some cases the fairly large discrepancy between calculated and observed structures can be partially attributed to mixed valency of the octahedral cations. For example, in both Ba\(_2\)TbBiO\(_6\) and Ba\(_2\)PrBiO\(_6\) there is a partial charge transfer from the rare-earth ion to the Bi atom, which gives rise to intermediate oxidation states of 3+/4+ for the rare-earth ion and 3+/5+ for bismuth (Harrison et al., 1995). In Ba\(_2\)PrBiO\(_6\), the situation is further complicated by octahedral site mixing of approximately 25%. In the absence of these effects the calculated atomic positions are in reasonably good agreement with the observed atomic positions.

Inspection of Table 4 also leads to some interesting observations regarding pseudosymmetry. First of all, note that regardless of the tilt angle the calculated value of the monoclinic angle, \(\beta\), remains exactly 90°. From this fact we infer that \(a^2b^-\) tilting creates a structure with monoclinic symmetry but a unit cell with orthorhombic dimensions. The small deviations from 90° that are observed must originate from distortions of the octahedra. Secondly, notice that, although the \(A\)-site cation is free to move anywhere on the mirror plane on which it sits, the displacement from \((0, 0, \frac{1}{2})\) is minimal in both the observed and the calculated structures. This fact is a validation of the argument made in the previous article that \(A\)-site cation displacements are negligible in tilt systems where only out-of-phase octahedral tilts occur. Finally, note that \(SPuDS\) consistently generates a unit cell where \(b > a\), and in some cases the two values differ significantly. This aspect of the calculations is not in very good agreement with the experimental observations. Among the experimental values not only is the difference between the lengths of the \(a\) and \(b\) axes considerably smaller than predicted; in some cases \(b < a\) in direct contradiction to the predictions. It is a general trend in both \(AMX_3\) and \(A_2MM'X_6\) perovskites and a number of tilt systems that \(SPuDS\) consistently predicts the splitting of the \(a\), \(b\) and \(c\) axes to be larger than observed experimentally. As \(SPuDS\) is fairly accurate in predicting the tilt angles, this discrepancy must originate in distortions of the octahedra. Why these distortions occur in such a way so as to minimize the distortion of the cell parameters from cubic values is not understood. We will return to this point in more detail in our treatment of \(P2_1/n\) \((a^-a^-b^-)\) perovskites.

**4.4. \(R3\) \((a^-a^-a^-)\)**

Equal tilts about all three axes of the cubic cell, tilt system \(a^-a^-a^-\), is the equivalent of a single tilt, \(\Phi\), about the \([111]\) direction of the aristotype structure. When rock-salt cation ordering and \(a^-a^-a^-\) tilting are combined the result is a structure with \(R3\) space-group symmetry. The fractional positions are \(A(x, x, x)\) with \(x \approx \frac{1}{3}\), \(M(0, 0, 0)\), \(M'(\frac{1}{3}, \frac{1}{3}, \frac{1}{3})\), and \(X(x, y, z)\) with \(x \approx \frac{1}{3}, y \approx \frac{1}{3}, z \approx \frac{1}{2}\). As with the \(a^2b^-\) tilt system there are relatively few reported examples of \(a^-a^-a^-\) tilting among ordered perovskites. Examples include...

Ba$_2$Bi$_3$Sb$_5$O$_{16}$ (Cox & Sleight, 1979), Ba$_2$Bi$_3$Sb$_5$O$_{16}$ (Fu, 2000), Ba$_2$Yb$_3$Bi$_5$O$_{16}$ (Harrison et al., 1995), Ba$_3$Bi$_4$O$_{16}$ (Zhou & Kennedy, 2005) and La$_3$Mn$_3$O$_{16}$ (M = Ni and Co; Bull et al., 2003). There are several similarities between the R3 (a $^{-}$a $^{-}$) and I2m (a $^{b}$b $^{b}$) tilt systems, including the prevalence of main group ions in high oxidation states and phase transitions between the two tilt systems. Both Ba$_2$Bi$_3$Sb$_5$O$_{16}$ and Ba$_3$Bi$_4$O$_{16}$ transform from I2/m (a $^{b}$b $^{b}$) to R3 (a $^{-}$a $^{-}$) upon warming. Among Ba$_3$MBO$_6$ compositions at room temperature there is a crossover from I2/m symmetry, observed for Ba$_2$YbBiO$_6$, as the ionic radius of the rare-earth ion decreases (Harrison et al., 1995). Both observations are indicative of a transformation from I2/m (a$^b$b$^b$) to R3 (a$^{-}$a$^{-}$) as the effective tolerance factor increases. Somewhat different behavior is reported for La$_3$Mn$_3$Co$_3$O$_{16}$ and La$_3$Mn$_3$Ni$_3$O$_{16}$. For these two compounds a transition from P2$_1$/m (a$^{-}$a$^{-}$) to R3 (a$^{-}$a$^{-}$) has been reported based on differential scanning calorimetry (DSC) data and analysis of neutron powder diffraction patterns collected at room temperature and elevated temperature, 623 K ($M = Ni$) and 673 K ($M = Co$). However, it has been shown that the P2$_1$/m (a$^{-}$a$^{-}$) to I2/m (a$^b$b$^b$) transition can be continuous (Howard et al., 2003), so it is quite possible that the actual sequence of phase transitions in these two compounds is $P2_1/m (a^{-}a^{-}) \Rightarrow I2/m (a^{b}b^{b}) \Rightarrow R3 (a^{-}a^{-})$. The failure to observe the I2/m phase may be attributed to the difficulty in detecting the continuous phase transition in a DSC measurement and the lack of neutron powder data across a more closely spaced temperature interval.

The lattice parameters and free fractional coordinates calculated by SPuDS are compared with the reported values in Table 5. In each calculation, SPuDS predicts the A-site cation to remain exactly on the high-symmetry position ($\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}$), although not required to do so by symmetry. This observation is consistent with the comments made in the previous section that out-of-phase octahedral tilting by itself does not induce displacements of the A-site cation. In the reported crystal structures the A-site cation position is not found exactly at ($\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}$), but in most cases the displacement away from this position is very small.

4.5. Pn3 (a$^{+}$a$^{+}$a$^{+}$)

The first example of a perovskite that exhibits a$^{+}$a$^{+}$a$^{+}$ tilting was reported by Deschanvres et al. (1967). Following this initial work, a sizeable family of compounds was produced through a sustained exploration of high-pressure high-temperature synthesis (Bochu et al., 1974; Chenavas et al., 1975; Ozaki et al., 1977). This family of perovskites has been the focus of considerable interest in recent years owing to the discovery of unusual dielectric properties in CaCu$_3$Ti$_4$O$_{12}$ (Subramanian et al., 2000). This is the only tilt system belonging to group B, where the A-site cations are not equivalent, that SPuDS has been programmed to model. This was a conscious decision based on the rarity of other tilt systems belonging to group B. The occurrence of a$^{+}$a$^{+}$a$^{+}$ tilting creates two sites for the A-site cations with very different chemical environments. For example, in CaCu$_3$Ti$_4$O$_{12}$ the Ca$^{2+}$ ion is icosahedrally coordinated with 12 Ca—O bonds of equal length [2.608 (1) Å], whereas the Cu$^{2+}$ ions have four very
short bonds [1.978 (1) Å] and a coordination environment that is close to square planar. The square planar environment is particularly favorable for small transition metal ions with a Jahn–Teller electron configuration, such as Cu$^{2+}$ or Mn$^{3+}$. Thus $a^a$-$a^a$ tilting goes hand in hand with 1:3 ordering of the $A$-site cations.

Perovskites with simultaneous 1:1 rock-salt ordering of the octahedral site cations and $a^a$-$a^a$ tilting, stabilizing 1:3 ordering of the $A$-site cations, crystallize with $Pn\bar{3}$ space-group symmetry. The fractional positions of the atoms are $A1 (\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$, $A2 (\frac{1}{2}, \frac{3}{2}, \frac{1}{2})$, $M (0, 0, 0)$, $M' (\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ and $X (x, y, z)$ with $x < \frac{1}{2}$, $y > \frac{1}{2}$ and $z > \frac{1}{2}$. The $a^a$-$a^a$ tilt system is different from those discussed thus far in one important aspect. This tilt system has little flexibility because any change in the tilt angle impacts the $A-X$ distances of the square-planar site much more dramatically than the $A-X$ distances of the icosahedral site. This effect tends to inhibit changes in the tilt angle that are brought about either by substitution of ions of varying size or by changes in temperature and/or pressure. This situation differentiates $a^a$-$a^a$ perovskites from all of the tilt systems that belong to group $A$ (see Table 1). It also means that the radii of all elements involved must be mutually compatible if a stable structure is to result. These facts make $SPuDS$ a particularly useful tool to guide synthetic attempts. In that spirit, $SPuDS$ was used in the structure prediction and analysis of dual $A$-$M$-site ordered CaCu$_3$, Ga$_3$Ta$_2$O$_{12}$, CaCu$_3$Ga$_5$Sb$_2$O$_{12}$ and CaCu$_3$Cr$_2$Sb$_2$O$_{12}$, as well as CaCu$_3$Ga$_5$Nb$_2$O$_{12}$ where the $M$-site cation distribution was disordered (Byeon et al., 2003, 2004, 2005). Prior to the synthesis of CaCu$_3$Ga$_5$M$_2$O$_{12}$ ($M =$ Sb and Ta) there were no reports in the literature of perovskites that simultaneously showed $a^a$-$a^a$ tilting and rock-salt order of the octahedral cations. The calculated structural variables for these two compounds are compared with the reported values in Table 6. The agreement is quite good. The GII values obtained via $SPuDS$ optimization for these two compounds in six different tilt systems is shown in Fig. 3(a). From this figure it is clear that the $a^a$-$a^a$ tilt system will be strongly preferred over competing quintary perovskite phases. Of course, it is more difficult to predict the stability with respect to multiphase mixtures.

The predicted stability of compositions of potential $Pn\bar{3}$ perovskites was briefly examined in a previous study (Byeon et al., 2003). A more detailed analysis of compounds predicted to favor crystallization in the space group $Pn\bar{3}$ was undertaken by identifying potential CaCu$_3$M$_2$M’$_2$O$_{12}$ combinations. An examination of likely candidates was undertaken using combinations of trivalent ($Al^{3+}$, $Co^{3+}$, $Cr^{3+}$, $Ga^{3+}$, $Ni^{3+}$, $Fe^{3+}$, $Rh^{3+}$, $Sc^{3+}$ and $In^{3+}$) and pentavalent ($V^{5+}$, $Ru^{5+}$, $Nb^{5+}$, $Ir^{5+}$, $Ta^{5+}$ and $Sb^{5+}$) octahedral site cations. This analysis led to 54 potential $Pn\bar{3}$ double perovskites, whose GII values are plotted versus tolerance factor in Fig. 3(b). The ideal tolerance factor for $Pn\bar{3}$ perovskites with CaCu$_3$M$_2$M’$_2$O$_{12}$ stoichiometry is roughly 0.87. The structure becomes less stable owing to the overbonding of the $Cu^{2+}$ ion and underbonding of the $Ca^{2+}$ ion for $\tau < 0.87$, while the opposite is true for $\tau > 0.87$. Interestingly, among all of the compounds modeled, CaCu$_3$Ti$_2$O$_{12}$ has the lowest GII. This fact helps to explain why it is one of the

**Figure 3**

(a) GII versus tilt system for CaCu$_3$Ga$_5$Ta$_2$O$_{12}$ (white) and CaCu$_3$Ga$_5$Sb$_2$O$_{12}$ (black). (b) GII versus tolerance factor of the $SPuDS$ optimized structures for $Pn\bar{3}$ perovskites. The tolerance factors of compounds containing these ions on the $M'$ site follow the order $Sb^{3+} < Ta^{5+} < Ir^{5+} < Nb^{5+} < Ru^{5+} < V^{5+}$.
few $a'a'a'$ perovskites that can be prepared without resorting to high-pressure synthesis. Based on the GII values for $A'A'MO_3$ compositions that have been prepared by high-pressure high-temperature synthesis techniques, it is reasonable to expect that compounds with a GII less than approximately 0.09 can form single-phase $a'a'a'$ perovskites (Lufaso & Woodward, 2001). The calculation values plotted in Fig. 5 reveal many compositions with GII < 0.09, indicating numerous potentially stable compositions. It is also interesting to ask what compositions might be formed if the A-site cations are not Ca$^{2+}$ and Cu$^{2+}$. The perovskites Sr$_{1-x}$Cu$_3$Ti$_3$O$_{12}$ (Li et al., 2004), SrMn$_3$Mn$_3$O$_{12}$ (Bochu et al., 1974) and SrCu$_3$Ru$_2$O$_{12}$ (Ebbinghaus et al., 2002) represent the only examples where Sr$^{2+}$ has replaced Ca$^{2+}$ on the icosahedral site. However, to the best of our knowledge, there have been no reports of SrCu$_3$M$_2$M$O_{12}$ perovskites. $SpuDS$ may be used to generate promising candidates for high-pressure high-temperature synthesis, which is described in a forthcoming paper.

### 4.6. $P2_1/n$ ($a'$ $a'$ $b'$)

Double perovskites with octahedral cation ordering and $a'$ $a'$ $b'$ octahedral tilting crystallize in the space group $P2_1/n$, which is the ordered perovskite equivalent of the GdFeO$_3$ structure (space group $Pnma$, tilt system $a'b'a'$). As is the case for $AMX_3$ perovskites, this is the most prevalent tilt system for ordered double perovskites. The octahedral cations are located on fixed positions $M (0, \frac{1}{2}, 0)$ and $M' (\frac{1}{2}, 0, 0)$, whereas the A-site cation and each of the three crystallographically distinct anions are located on general positions. Four example compounds – La$_2$NiRuO$_6$ (Seinen et al., 1987), Sr$_2$ErRuO$_6$ (Battle et al., 1991), Ca$_2$SbFeO$_6$ (Lee et al., 1997) and La$_2$LiSbO$_6$ (López et al., 1992) – were chosen to illustrate the accuracy of the $SpuDS$ structure calculations in detail. The calculated structures are compared with those reported in the literature in Table 7. A broader evaluation of the accuracy of $SpuDS$ for predicting structures of $P2_1/n$ perovskites is displayed in Figs. 4 and 5. A complete list of the compounds that were used to generate Figs. 4 and 5 can be found in the supporting material. These figures clearly show that as the tolerance factor decreases the tilt angle systematically increases, as do the $x$ and $y$ coordinates of the A-site cation. The calculated variation of the tilt angle with tolerance factor is in very good agreement with the observed tilt angles. A similar degree of accuracy was previously reported for $AMX_3$ perovskites (Lufaso & Woodward, 2001).

The octahedral tilt angle used in $SpuDS$ is a single tilt angle that is a combination of the rotation about a [110] axis and a [001] axis normal to the original, which was described previously for the $Pnma$-type perovskites (O’Keeffe & Hyde, 1977). A coupled tilt angle is utilized because the two tilt angles are not truly independent tilt angles but are related in the rigid octahedral assumption. The $TUBERS$ software calculated the tilt angle for both the coupled octahedral tilt angle and the individual tilt axes. The single coupled octahedral tilt angle is plotted versus tolerance factor in Fig. 5(a), while the relationship between the single coupled tilt angle and the individual tilt angles about the [110] and [001] axes are shown in Fig. 5(b).

There is an essentially linear relationship between the calculated value of the A-site cation displacement in the $xy$ plane and the tolerance factor. The experimental values follow the same general trend, albeit with a considerable amount of scatter in the data, but unlike the calculated trend the A-site cation displacement tends to saturate as the tolerance factor decreases. Even for moderate degrees of tilting $SpuDS$ tends to slightly overestimate the displacement of the A-site cation. The $z$ coordinate of the A-site cation deviates very little from

5. The observed value of an average tilt angle was calculated from the fractional coordinates of the oxygen ions, $M-X$ distances and lattice parameters using the program $TUBERS$. |
the value it would possess in the absence of tilting. Furthermore, it shows no dependence on the tolerance factor. This observation is not unexpected, because in $AMX_3$ perovskites that undergo $a\frac{a}{a'}b'$ tilting the $A$-site cation lies on a mirror plane and the $A$-site position is $(x, y, \frac{1}{2})$ (using the $Pbnm$ setting). While the different identities and sizes of the $M$ and $M'$ cations destroy the strict symmetry of the mirror plane, the oxygen ions are still related by a pseudo-mirror plane unless the $M$ and $M'$ cations differ significantly in size. As discussed in the preceding article many perovskites exhibit a high degree of pseudosymmetry. Furthermore, it was suggested that the pseudosymmetry exhibited by $Sr_2M^{3+}M^{5+}O_6$ perovskites was more pronounced than the pseudosymmetry of $Ca_2M^{3+}M^{5+}O_6$ perovskites (Barnes et al., 2006). To investigate this further a comparison of the reduced

(b) The average octahedral tilt angles of $a\frac{a}{a'}b'$ $P2_1/n$ perovskites calculated from the experimental cell parameters and atomic coordinates using the equations of Groen et al. (1986). The $x$ axis is the average octahedral tilt angle calculated using a coupled tilt angle and the $y$ axis contains the octahedral tilt angle about the $[001]$ (filled triangles) and $[110]$ (open squares) axes.
pseudo-cubic lattice parameters for $\text{Sr}_2M^{3+}M^{5+}O_6$ and $\text{Ca}_2M^{3+}M^{5+}O_6$ monoclinic perovskites is shown in Fig. 6. Reduced pseudo-cubic lattice parameters are useful for comparing cell constants of perovskites that cover a large range of unit-cell volumes. They are calculated by converting each of the three lattice parameters into a value that is $\sim 2a_p$, where $a_p$ is the cubic cell edge of a $Pm\bar{3}m$ perovskite. The deviation from an orthorhombic cell is neglected, which is a valid approximation because $\beta \approx 90^\circ$ in almost all cases (see also Fig. 6c). After converting the lattice parameters to their pseudo-cubic counterparts, the reduced lattice parameters were computed using cell constants found in the literature for Ca and Sr compounds, and theoretical values were determined by SPuDS using the equation

$$a_r = \frac{a_{pc}}{V^{1/3}},$$

where $a_r$ is the reduced lattice parameter, $a_{pc}$ is the pseudo-cubic cell constant ($= 2a_p$) and $V$ is $2a_p^2b \times c$. If $a_r$, $b_r$, and $c_r$ are all equal to 1, the lattice is metrically cubic. As the lattice metric distorts from cubic, $a_r$, $b_r$, and $c_r$ will deviate from 1. Figs. 6(a) and 6(b) show that the magnitude of the orthorhombic distortion is calculated to increase smoothly for both strontium and calcium compounds as octahedral tilting increases. The value of the monoclinic angle $\beta$ is plotted in Fig. 6(c). The calculated values of $\beta$ deviate very little from $90^\circ$ showing that the basic orthorhombic unit-cell dimensions are essentially preserved by tilting of rigid octahedra. The reason for the inherent orthorhombic pseudosymmetry can be traced to the fact that $a'$ $a''b''$ tilting by itself only lowers the symmetry to orthorhombic. The further reduction to monoclinic symmetry occurs in response to cation ordering. Much like the displacement of the $A$-site cation in the $z$ direction, there is little driving force for deviation from the orthorhombic value unless the radii of the $M$ and $M'$ cations differ significantly.

The experimental values plotted in Fig. 6 reveal a more complicated situation. For $\text{Ca}_2M'^{3+}O_6$ perovskites the orthorhombic distortion increases with decreasing tolerance factor, following the basic trend predicted by SPuDS. The calculated distortion of the unit cell is somewhat larger than the actual distortion, following the trend observed in every previous tilt system. More than anything else this discrepancy between calculation and experiment probably indicates that while tilting of rigid octahedra is the primary mechanism for obtaining the lowest-energy configuration, small distortions of the octahedra play a secondary role in this process. The situation is very different for $\text{Sr}_2M'^{3+}O_6$ perovskites. Here the reduced cell parameters are all closely bunched around 1.00 and show little dependence on tolerance factor. Part of this result can be attributed to the fact that the tolerance factors of $\text{Sr}_2M'^{3+}O_6$ perovskites do not go much below $\tau = 0.92$. Nonetheless, over the tolerance factor range where both $\text{Sr}_2M'^{3+}O_6$ and $\text{Ca}_2M'^{3+}O_6$ compounds coexist the orthorhombic distortion of the strontium compounds is on average much smaller than that of the calcium compounds. This effect is not limited to ordered perovskites; it also exists for ternary

---

**Figure 6**

Reduced lattice parameter versus tolerance factor for monoclinic (a) $\text{Ca}_2M^{3+}M^{5+}O_6$ and (b) $\text{Sr}_2M^{3+}M^{5+}O_6$ double perovskites. Circles represent $a$, squares represent $b$ and triangles represent the $c$ pseudo-cubic lattice parameter. Thick lines represent $a$, dotted lines represent $b$, and dashed lines represent $c$-reduced lattice parameters predicted by SPuDS. (c) Monoclinic $\beta$ angle, where open and filled symbols (circles: $\text{Sr}_2M^{3+}M^{5+}O_6$; triangles: $\text{Ca}_2M^{3+}M^{5+}O_6$) represent literature and SPuDS predicted double perovskites, respectively.
perovskites. Consider, for example, the reduced lattice parameters of the \( Pbnm \) perovskite \( \text{CaTiO}_3 \) (\( \tau = 0.946 \)), \( a_r = 0.9937 \), \( b_r = 1.0069 \) and \( c_r = 0.9994 \) (Ranjan et al., 1999) in comparison to \( \text{SrSnO}_3 \) (\( \tau = 0.957 \)), \( a_r = 1.0007 \), \( b_r = 0.9997 \) and \( c_r = 0.9996 \) (Green et al., 2000). While both compounds have considerable pseudo-cubic character, the deviations of \( a_r \) and \( b_r \) in \( \text{CaTiO}_3 \), which are the two parameters most sensitive to tilting, deviate from unity by an amount that is an order of magnitude larger than in \( \text{SrSnO}_3 \). The origin of this effect is not understood. It is a question that warrants further theoretical consideration.

5. Conclusions

The software program \( SPuDS \) has been developed for predicting the crystal structures of perovskite compounds, including those with multiple octahedral cations and octahedral tilting distortions. Detailed analysis of the results for several octahedral tilt systems and a large number of compounds indicates that the method is an accurate approach to modeling the crystal structures of ordered perovskites. Calculated global instability index (GII) values are useful in determining the relative stability of the composition in a particular tilt system. A large difference in GII for untitled and tilted compositions implies that the structure is relatively unstable and likely to undergo an octahedral tilting distortion. Structures reported in the literature with a large GII that were unstable and likely to undergo an octahedral tilting distortion have occurred and the true symmetry is lower.

In general, crystal structures predicted using \( SPuDS \) provide a useful and reliable starting model for Rietveld refinements. Thus, it can be used to simplify the structure refinement process, particularly for perovskites crystallizing in space groups with many degrees of freedom (e.g. \( P2_1/n \)). A comparison of predicted and observed structures reveals a tendency for the unit-cell parameters to distort somewhat less than expected for rotations of rigid octahedra. This tendency for enhanced pseudosymmetry is particularly pronounced in \( \text{Sr}_2\text{MM}’\text{O}_6 \) perovskites.
